(Received 12 December 1996; accepted for publication 12 May 1997)

The room-temperature wall energy $\sigma_w = 4.0 \times 10^{-3} \text{ J/m}^2$ of an exchange-coupled $\text{Tb}_{19.6}\text{Fe}_{74.7}\text{Co}_{5.7}/\text{Dy}_{28.5}\text{Fe}_{43.2}\text{Co}_{28.3}$ double layer stack can be reduced by introducing a soft magnetic intermediate layer in between both layers exhibiting a significantly smaller anisotropy compared to Tb-FeCo and Dy-FeCo. σ_w will decrease linearly with increasing intermediate layer thickness, d_{IL} , until the wall is completely located within the intermediate layer for $d_{\text{IL}} \geq d_w$, where d_w denotes the wall thickness. Thus, d_w can be obtained from the plot σ_w versus d_{IL} . We determined σ_w and d_w on Gd-FeCo intermediate layers with different anisotropy behavior (perpendicular and in-plane easy axis) and compared the results with data obtained from Brillouin light-scattering measurements, where exchange stiffness, A , and uniaxial anisotropy, K_u , could be determined. With the knowledge of A and K_u , wall energy and thickness were calculated and showed an excellent agreement with the magnetic measurements. A ten times smaller perpendicular anisotropy of $\text{Gd}_{28.1}\text{Fe}_{71.9}$ in comparison to Tb-FeCo and Dy-FeCo resulted in a much smaller $\sigma_w = 1.1 \times 10^{-3} \text{ J/m}^2$ and $d_w = 24 \text{ nm}$ at 300 K. A $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ with in-plane anisotropy at room temperature showed a further reduced $\sigma_w = 0.3 \times 10^{-3} \text{ J/m}^2$ and $d_w = 17 \text{ nm}$. The smaller wall energy was a result of a different wall structure compared to perpendicular layers. © 1997 American Institute of Physics. [S0021-8979(97)02616-9]

I. INTRODUCTION

Magneto-optical (MO) single layer disks based on amorphous rare-earth (RE) transition-metal (TM) alloys such as Tb-FeCo and Dy-FeCo exhibit very good recording properties such as high carrier-to-noise ratio, and low required write/erase laser powers, and fields.^{1,2} The storage capacity of current MO disks has been increased by a factor of 4 compared to the first products. Due to several different approaches regarding recorder hardware, data processing, storage formats, and the use of exchange-coupled MO layers, this development will continue, and a disk capacity that is sufficient for consumer audio and video applications will be achieved in the near future.^{3,4}

The interface wall energy σ_w determines the switching fields of an exchange-coupled double layer stack. One can adjust the wall energy independently from the magnetic properties of the other layers by introducing an additional intermediate layer. The reduction of σ_w depends on intermediate layer thickness d_{IL} , and the fraction of the wall located within the intermediate layer. The latter depends on the intrinsic wall thickness d_w of an intermediate layer, which is a function of anisotropy and exchange stiffness. A $\text{Gd}_{28.1}\text{Fe}_{71.9}$ with a perpendicular anisotropy and a $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ with an in-plane anisotropy at room temperature were tested as intermediate layers. σ_w and d_w were determined as a function of intermediate layer thickness. Exchange stiffness and anisotropy of Gd-Fe single layer samples were determined by Brillouin light-scattering and magnetic torque measurements. From these results, also σ_w and d_w were calculated and compared to the results of triple layer stacks.

II. SAMPLE PREPARATION AND EXPERIMENTAL CONDITIONS

The exchange-coupled films were deposited by dc-magnetron sputtering. The cathodes were mounted in a Balzers BAK 600 deposition chamber with a target-substrate distance between 6.6 and 7.9 cm. The substrates were mounted on a holder rotating at 1 Hz, and were moved alongside the cathode during deposition to obtain a homogeneous composition and layer thickness. The $\text{Tb}_{19.6}\text{Fe}_{74.7}\text{Co}_{5.7}/\text{Dy}_{28.5}\text{Fe}_{43.2}\text{Co}_{28.3}$ double layers were sputtered at an argon pressure of 0.55 Pa and a power density (PD) of 1.3 W/cm^2 . The triple layer stacks have additional intermediate layers $\text{Gd}_{28.1}\text{Fe}_{71.9}$ ($P_{\text{Ar}} = 1.2 \text{ Pa}$, $PD = 1.0 \text{ W/cm}^2$) and $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ ($P_{\text{Ar}} = 2.1 \text{ Pa}$, $PD = 2.0 \text{ W/cm}^2$). The background pressure was $2 \times 10^{-5} \text{ Pa}$. The MO layer stack was coated for chemical protection purposes with a Ti reflective layer of 26 nm thickness. The composition was determined by electron-probe microanalysis.

All samples were magnetically characterized between 90 and 600 K, yielding saturation magnetization $M_s(T)$, coercivity $H_c(T)$, and switching fields H^\pm of exchange-coupled multilayer stacks. M_s and H_c were measured with a vibrating sample magnetometer; H^\pm were determined with a Hall magnetometer. The anisotropy $K_u(T)$ was measured with a torque magnetometer. However, the method is only applicable to single layers. Compensation temperature T_{comp} and Curie temperature T_C were derived from the magnetic data.

The Brillouin light-scattering (BLS) experiments were performed on $\text{Gd}_{28.1}\text{Fe}_{71.9}$ layers with thicknesses between 20 and 50 nm. The layers were covered with a 200 nm Al layer to protect the samples from thermal overheating in the

laser spot. The laser light of about 30 mW was focused onto the film through the transparent substrate. A magnetic field of about 2300 kA/m was applied parallel to the film plane to ensure that the layers were in-plane magnetized. The BLS measurements provide data of the exchange stiffness A and the gyromagnetic factor g_{eff} at room temperature.

III. RESULTS AND DISCUSSION

A. Brillouin light scattering

Brillouin light scattering is the measurement of the inelastically scattered light from dynamic excitations, which in the present case, are the so-called dipolar Damon–Eshbach mode and the standing spin-wave modes. The Damon–Eshbach mode is a surface mode, and its frequency depends on the magnetization and anisotropy contributions. Standing spin-wave modes are modes with their wave vector quantized perpendicular to the film, and their frequencies depend in addition on the exchange stiffness constant, A . For these modes, apart from the crossing regime with the Damon–Eshbach mode, the frequencies show a characteristic decrease proportional to the inverse of the square of the layer thickness. In our experiments, the Damon–Eshbach mode, as well as the first and second standing spin-wave modes, could be observed. A fit to the experimentally obtained spin-wave frequencies was performed within the framework of a suitable model, which includes all details of spin-wave dispersion.⁵ The exchange stiffness, A , and the effective Landé factor, g_{eff} , were used as fit parameters. g_{eff} is a weighted average of the g factors of the Fe and Gd sublattices, and is defined by the equation for the gyromagnetic ratio, $\gamma = 1/2 \gamma_e g_{\text{eff}}$, where γ_e is the free-electron value. The uniaxial anisotropy $K_u = 0.34 \times 10^5 \text{ J/m}^3$ and the saturation magnetization $M_s = 102 \text{ kA/m}$, were used as input parameters. The data were obtained from magnetic measurements on sputtered $\text{Gd}_{28.1}\text{Fe}_{71.9}$ single layer samples. For the exchange stiffness, we obtained $A = (1.7 \pm 0.5) \times 10^{-12} \text{ J/m}$, and for the effective Landé factor $g_{\text{eff}} = 1.3 \pm 0.3$. The value for A is in agreement with results of the systems Gd–Co, GdTb–Fe, and GdNd–Fe.^{6,7} A literature value for $\text{Gd}_{33}\text{Fe}_{67}$ (Ref. 8) of $A = 3.6 \times 10^{-12} \text{ J/m}$ seems to be too large. The effective Landé factor is in good agreement with data reported by Ng *et al.*⁹ The exchange stiffness A mainly depends on the Curie temperature T_C , if very similar RE–TM alloys are compared.¹⁰ $\text{Gd}_{28.1}\text{Fe}_{71.9}$ and $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ have very similar T_C of 515 and 500 K, respectively. Therefore $A = (1.7 \pm 0.5) \times 10^{-12} \text{ J/m}$ can also be assumed for Gd–FeCo. From exchange stiffness and anisotropy, the wall energy and wall thickness of the investigated layers can be calculated, see the next section.

B. Magnetic measurements

The switching fields for a magnetic reversal of a layer as part of an exchange-coupled double layer stack differs from H_c of the same layer, if single and uncoupled. The reversal of each individual layer will lead to the creation (+) or annihilation (–) of an interface wall, as shown in Fig. 1 for a Tb–FeCo/Dy–FeCo double layer at 350 K. The interface

FIG. 1. Hysteresis loop of a $\text{Tb}_{19.6}\text{Fe}_{74.7}\text{Co}_{5.7}/\text{Dy}_{28.5}\text{Fe}_{28.5}\text{Co}_{28.3}$ double layer sputtered at an argon pressure of 0.55 Pa and a power density of 1.3 W/cm^2 . The layer thicknesses were 52 and 100 nm, respectively. The dashed loop represents the minor loop of the Dy–FeCo layer. The fields H^\pm represent the switching fields for creation (+) and annihilation (–) of an interface wall. The indices (m) and (r) denote the Tb–FeCo and Dy–FeCo layers, respectively.

wall energy σ_w resulted from the difference between the switching fields of the minor loop H^+ for creation and H^- for annihilation of an interface wall¹¹

$$\sigma_w = \mu_0 M_s d (H^+ - H^-), \quad (1)$$

where M_s and d denote the saturation magnetization and thickness of the switched Dy–FeCo layer. For $M_s = 80 \text{ kA/m}$ and $d = 100 \text{ nm}$, we determined a wall energy of $3.1 \times 10^{-3} \text{ J/m}^2$ at 350 K. At 300 K, the Tb–FeCo could not be switched due to its large coercivity, but the determined minor loop of the Dy–FeCo layer revealed a wall energy of $4.0 \times 10^{-3} \text{ J/m}^2$.

The triple layer stacks have one additional soft magnetic layer (intermediate layer) between the Tb–FeCo and Dy–FeCo layers. Then, the wall energy also depends on magnetic properties and the thickness of the intermediate layer. The tested intermediate layers showed a smaller anisotropy compared to Tb–FeCo and Dy–FeCo. Because the wall energy is a function of anisotropy, it will decrease if the wall is located within a layer with a smaller anisotropy. The contribution of the intermediate layer to the total wall energy depends on its layer thickness d_{IL} . A thicker intermediate layer contains a larger fraction of the interface wall resulting in a decrease of σ_w for increasing d_{IL} . If d_{IL} is larger than the wall thickness d_w , the wall will be totally located in the intermediate layer. Then σ_w cannot be reduced further, and the measured σ_w corresponds to the intrinsic wall energy of the intermediate layer, and it will be independently from d_{IL} for $d_{\text{IL}} \geq d_w$. The thickness d , where the decrease of σ_w stops, corresponds to the wall thickness d_w .

The tested intermediate layers $\text{Gd}_{28.1}\text{Fe}_{71.9}$ ($T_C = 515 \text{ K}$, $T_{\text{comp}} = 390 \text{ K}$) and $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ ($T_C = 500 \text{ K}$, $T_{\text{comp}} > T_C$) showed different anisotropy behaviors. For $\text{Gd}_{28.1}\text{Fe}_{71.9}$, we determined a perpendicular anisotropy $K_u = 0.34 \times 10^5 \text{ J/m}^3$ at 300 K, as shown in Fig. 2. This is approximately one order of magnitude smaller in comparison

FIG. 2. Uniaxial anisotropy K_u , effective anisotropy K_{eff} , and saturation magnetization M_s of a $\text{Gd}_{28.1}\text{Fe}_{71.9}$ single layer (thickness 50 nm) as function of temperature.

to Tb–FeCo and Dy–FeCo,^{6,10} and corresponds to measurements on evaporated $\text{Gd}_{1-x}\text{Fe}_x$ layers, where a perpendicular anisotropy was found for $0.70 < x < 0.82$.¹²

Evaporated $\text{Gd}_{1-x}\text{Co}_x$ alloys showed allways in-plane anisotropy. The addition of certain amount of Co to Gd-rich Gd–Fe alloys causes in-plane anisotropy at room temperature. On evaporated Gd–FeCo alloys, no perpendicular anisotropy was found for Co/Fe ratios larger than 0.47. Samples with a smaller Co/Fe ratio showed a temperature range with in-plane anisotropy, which was a function of Gd content.¹² For sputtered samples, we also expected an in-plane anisotropy at a suitable Co content. $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ showed in-plane anisotropy below 335 K, where a large saturation magnetization led to a negative $K_{\text{eff}} = K_u - \mu_0/2M_s^2$ despite a $K_u > 0$, as shown in Fig. 3. For $T > 335$ K, the uniaxial anisotropy K_u is larger than $\mu_0/2M_s^2$, resulting in a perpendicular anisotropy. For the in-plane intermediate layer, the magnetic moments at the middle of the interface wall are aligned parallel to the easy axis of the intermediate layer. Therefore, we expected a different function $\sigma_w(d_{\text{IL}})$ for Gd–FeCo intermediate layers in comparison to Gd–Fe layers with perpendicular anisotropy.

FIG. 3. Uniaxial anisotropy K_u , effective anisotropy K_{eff} , and saturation magnetization M_s of a $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ single layer (thickness 51 nm) as function of temperature.

FIG. 4. Wall energy σ_w as a function of intermediate layer thickness d_{IL} for (○) $\text{Gd}_{28.1}\text{Fe}_{71.9}$ and (●) $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ at 300 K. The thickness of Tb–FeCo and Dy–FeCo layers was 22.0 and 50.4 nm, respectively. The solid lines were calculated from BLS data using Eqs. (2)–(4).

Wall energy and wall thickness are determined by the minimum of the total wall energy $\int (E_{\text{ex}} + E_K + E_H + E_D) dz = \text{minimum}$, where E_{ex} , E_K , E_H , and E_D denote the exchange energy, anisotropy energy, field energy, and demagnetizing energy, respectively. E_H/K_u is smaller than 0.2 for (Gd,Tb)–(Fe,Co) and (Gd,Dy)–(Fe,Co) layers.^{6,10} This is more than ever valid for corrections due to the demagnetizing energy scaling with M_s^2 , which is much less than $H^\pm M_s$. In this case, walls can be treated as classic 180° Bloch walls.¹³ Then, wall energy σ_w and thickness d_w are given by¹⁴

$$\sigma_w = 4\sqrt{AK_u} \quad d_w = \pi\sqrt{A/K_u}. \quad (2)$$

Both equations can be applied for double and triple layer stacks, if all layers exhibit perpendicular anisotropy, i.e., Gd–Fe intermediate layers. Figure 4 shows the wall energy as a function of intermediate layer thickness d_{IL} for triple layer measurements and data calculated from Brillouin light-scattering measurements. The result for exchange-coupled double layers corresponds to the wall energy of Tb–FeCo and Dy–FeCo single layers, assuming typical values for exchange stiffness A and anisotropy K_u . With $A = 3.1 \times 10^{-12}$ J/m and $K_u = 3.2 \times 10^5$ J/m³,^{6,10} a wall energy of 4.0×10^{-3} J/m² was expected, which was in an excellent agreement with the magnetic measurement. For $\text{Gd}_{28.1}\text{Fe}_{71.9}$, a minimum wall energy of $1.1 \pm 0.1 \times 10^{-3}$ J/m² was obtained for intermediate layer thicknesses $d_{\text{IL}} \geq d_w$. From BLS data [$K_u = 0.34 \times 10^5$ J/m³ and $A = (1.7 \pm 0.5) \times 10^{-12}$ J/m], a wall energy of $(1.0 \pm 0.2) \times 10^{-3}$ J/m² was calculated using Eq. (2). The triple layer measurements revealed a wall thickness d_w of 24 ± 2 nm. A wall thickness of 22 ± 3 nm was determined from BLS data. Both results were in excellent agreement.

In the case of intermediate layers with in-plane anisotropy, the wall structure is not a simple 180° Bloch wall. The magnetic moments at the interface to the Tb–FeCo and Dy–FeCo layers are aligned parallel to the perpendicular easy axis of the Tb–FeCo and Dy–FeCo layers. But the magnetic

moments in the middle of the wall are parallel to the in-plane easy axis of the $\text{Gd}_{34.1}\text{Fe}_{61.4}\text{Co}_{4.5}$ layer. Therefore, one can consider this type of wall as the sum of two 90° walls, where the easy axis of both sides of a 90° wall are perpendicular to each other. Lilley calculated solutions of $\int (E_{\text{ex}} + E_K + E_H + E_D) dz = \text{minimum}$ for walls in materials with two easy axes not parallel to each other.¹⁵ Then, the energy and thickness of 90° walls are given by¹⁶

$$\sigma_w(\text{Gd-FeCo}) = 2 \times \sigma_w(90^\circ) = 2 \sqrt{A K_u}, \quad (3)$$

$$d_w(\text{Gd-FeCo}) = 2 \times d_w(90^\circ) = \sqrt{8 \ln 2} \sqrt{A/K_u}. \quad (4)$$

Inserting magnetically measured $K_u = 0.25 \times 10^5 \text{ J/m}^3$ and $A = (1.7 \pm 0.5) \times 10^{-12} \text{ J/m}$, obtained from BLS measurements, the wall energy and wall thickness of Gd-FeCo triple layers should be $(0.4 \pm 0.1) \times 10^{-3} \text{ J/m}^2$ and $(19 \pm 3) \text{ nm}$, respectively. Switching field experiments on Gd-FeCo triple layers revealed an interface wall energy of $(0.3 \pm 0.1) \times 10^{-3} \text{ J/m}^2$ and a wall thickness of $(17 \pm 1) \text{ nm}$, see Fig. 4. Also, for Gd-FeCo, an excellent agreement between the BLS data and triple layer measurements was obtained. This also shows that the interface wall of the triple layer with an in-plane intermediate layer can be treated as a double 90° wall.

The wall energy measurements of triple layer stacks with a varied thickness of intermediate layers enables the determination of the wall thickness of the used intermediate layer. The method can be applied to magnetic layers, which the anisotropy is significantly smaller than the K_u of Tb-FeCo and Dy-FeCo of approximately $3.0 \times 10^5 \text{ J/m}^3$. This applies to a large number of magnetic alloys. With this method, wall

thicknesses down to 10 nm can be easily determined only using a hysteresis loop and a vibrating sample magnetometer. With other techniques, like optical or magnetic force microscopes, it is more difficult to obtain a resolution better than 50 nm.
